e-mail: anne.decourchelle@cea.fr

Abstract. A review of the main issues in the field of particle acceleration in Supernova Remnants is provided in the context of future X-ray observations with *Simbol-X*. After a summary of the nonthermal acceleration mechanisms at work, I briefly review the observations of supernova remnants in hard X-rays and in gamma rays. Open issues are discussed in this framework.

Key words. ISM: supernova remnants – X-rays: ISM – Gamma rays: observations – Acceleration of particles – Radiation mechanisms: non-thermal – Shock waves –

1. Introduction

Supernova remnants (SNRs) are expected to be the main source of cosmic rays with energies up to the knee at $\approx 3 \cdot 10^{15}$ eV (see for a discussion Drury et al., 2001). The ejection of high velocity material during the explosion gives rise to a shock that both heats the ambient medium to millions degrees and accelerates particles.

While the millions degrees gas emits thermal X-rays below 10 keV, the accelerated charged particles produce non-thermal emission over the entire electromagnetic spectrum through four main emission mechanisms. First, the accelerated electrons produce synchrotron emission when spiraling in a magnetic field. This emission, extending from the radio to X-ray domains, corresponds to a population of GeV and TeV accelerated electrons, respectively. The population of TeV electrons, observed in

X-ray synchrotron, gives also rise to Inverse Compton emission: they communicate a large part of their energy to low energy photons (from the Cosmic Microwave Background or from the local optical and infrared environment), which then reach gamma ray energies. Non-thermal bremsstrahlung is produced by the population of supra-thermal and relativistic electrons when their trajectory is deflected by the electrical field of positive ions: their emission extends from hard X-rays to gamma rays. Finally, the interaction of accelerated protons with those of the ambient medium produces pions. The neutral π^0 decays almost instantaneously and produces gamma rays in the GeV - TeV range.

Supernova remnants are well known to be sources of radio synchrotron emission. The first suggestion of such an association dates from 1954 (Hanbury Brown, 1954), and was rapidly confirmed by Baldwin & Edge (1957). The observed radio shell morphology supports

Send offprint requests to: A. Decourchelle

the view that particles (notably electrons) have been accelerated to GeV energies at the shock of SNRs.

2. Previous X-ray observations

While radio synchrotron emission is observed in most SNRs (in 203 over the 217 observed Galactic SNRs, Green 2004), X-ray synchrotron emission is observed only in a few remnants up to now. The first evidence of such emission in a shell-like supernova remnant was obtained in SN1006 with *ASCA* (Koyama et al., 1995). *ASCA* was the first X-ray satellite able to resolve the spectra of the two bright bilateral rims of SN 1006. This provided the first proof that shocks in supernova remnants were able to accelerate particles (electrons) up to TeV energies. This discovery was followed by the detection with *ASCA* of X-ray synchrotron emission in RX J1713.7-3946 (Koyama et al., 1997; Slane et al., 1999), Vela Junior (Slane et al., 2001), and RCW 86 (Bamba et al., 2000). Since then, these sources have been observed in X-rays in much more details with *XMM-Newton* and *Chandra* (Uchiyama et al., 2003; Cassam-Chenaï et al., 2004b; Iyudin et al., 2005; Bamba et al., 2005; Vink et al., 2006), and in the gamma rays with the *H.E.S.S.* and *CANGAROO-II* Cherenkov telescopes (Katagiri et al., 2005; Aharonian & al., 2006; Aharonian et al., 2007). Apart from these synchrotron-dominated shell SNRs, X-ray synchrotron emission has been detected as well in the younger ejecta-dominated SNRs, mainly in Tycho (Hwang et al., 2002), Cas A (Vink & Laming, 2003) and Kepler (Cassam-Chenaï et al., 2004a; Reynolds et al., 2007). For Cas A, there is also evidence for TeV emission (Aharonian et al., 2001). Above 10 keV, a number of young SNRs show a hard X-ray tail observed with *RXTE*, *BeppoSax* and *INTEGRAL*: Cas A (Allen et al., 1997; Renaud et al., 2006), Tycho, Kepler, SN 1006 and RCW 86 (Allen et al., 1999). However, as no spectro-imagery is available above 10 keV, the nature of the emission there is still unknown. Different origins may be invoked: Thermal emission from

a very high temperature shocked ambient interstellar medium ? Synchrotron emission from relativistic electrons accelerated at the forward shock ? Non-thermal bremsstrahlung from suprathermal electrons accelerated at the contact discontinuity (interface between shocked ejecta and shocked ambient medium) ?

Spatially resolved spectroscopy above 10 keV is required to observe, to distinguish and to quantify the different contributions of the non-thermal X-ray emission in SNRs. We need *Simbol-X* to study the nature of the emission and to answer a number of pending questions on shock physics and particle acceleration.

3. Shock physics and particle acceleration

3.1. Shock physics

SNRs produce very high Mach number shocks, that propagate generally in a low density ambient medium ($< 1 \text{ cm}^{-3}$). In such conditions, collective plasma processes play a non-negligible role compared to Coulomb collisions (Ghavamian et al., 2007) and this directly affects the degree of temperature equilibration at the shock between the electrons and the ions. Quantifying with *Simbol-X* the contribution of the thermal emission above 10 keV provides strong constraints on the presence of a high electronic temperature in the shocked ambient medium. If the thermal emission appears to be important, this will impose an efficient heating of the electrons at the shock through collision-less processes, as well as constraints on the supernova kinetic energy. However, the faint level of thermal emission observed below 10 keV in Tycho (Cassam-Chenaï et al., 2007) and SN 1006 (Acéro et al., 2007) does not favor a thermal origin of the hard X-ray emission.

3.2. Electron acceleration

Electrons are only about 2% of cosmic rays (Ferrière, 2001), but they can reveal a lot on the mechanism of diffusive shock acceleration, as they are accelerated like protons.

3.2.1. What is the maximum energy of accelerated particles ?

A key question for understanding particle acceleration in SNRs lies in knowing the maximum energy of accelerated particles. This can be obtained through the measurement of the cut-off frequency of the synchrotron emission, observable in X-rays, and knowing the magnetic field. Typical values are in the order of 80 TeV assuming a $10\mu\text{G}$ magnetic field (Reynolds & Keohane, 1999).

Another important issue on particle acceleration is its dependence to the magnetic field orientation. In SN 1006, very strong azimuthal variations of the maximum energy of electrons have been observed with *XMM-Newton* (Rothenflug et al., 2004), whose amplitude cannot be explained by variations of the magnetic compression alone as proposed by Reynolds (1996). As detailed in Rothenflug et al. (2004), the very low synchrotron brightness in the interior of SN 1006 favors a geometry, where the bright non-thermal limbs are polar caps rather than an equatorial belt. In addition, the maximum energy of accelerated particles is higher at the bright limbs than elsewhere. If the magnetic field is amplified at the limbs, the maximum energy is certainly much larger there (> 1000 TeV) than outside the limbs ($E \approx 25$ TeV if $B \approx 10\mu\text{G}$). The X-ray synchrotron geometry of SN 1006 favors cosmic-ray acceleration where the magnetic field was originally parallel to the shock speed.

There are thus two main objectives on this issue well designed for *Simbol-X*:

- to get a precise determination of the cut-off energy using the full extent of the synchrotron spectrum above 10 keV.
- to measure the azimuthal variations of the maximum energy using spatially resolved spectroscopy including energies above 10 keV.

3.2.2. How large is the magnetic field ?

The comparison of the radio and X-ray synchrotron morphologies provide constraints on the downstream magnetic field. In a number of SNRs, the X-ray syn-

chrotron emission exhibits a filamentary emission just behind the blast wave. This is observed in historical (Hwang et al., 2002; Vink & Laming, 2003; Bamba et al., 2005) and in synchrotron-dominated (Uchiyama et al., 2003; Bamba et al., 2005) remnants.

Two explanations have been proposed to interpret that: either the magnetic field is large enough ($\approx 100\mu\text{G}$) to induce strong radiative losses in the high energy electrons (Vink & Laming, 2003; Ballet, 2006), or the magnetic field is damped at the shock (Pohl et al., 2005).

These models predict distinct morphology and spectral shape in X-rays and radio (Cassam-Chenaï et al., 2007), but the spectrum must be observed over a broad band extending to hard X-rays to tell one from the other. While the expected spatial resolution of *Simbol-X* is not relevant for studying arcseconds wide filaments, its sensitivity above 10 keV is perfectly suited for constraining the shape of the hard X-ray spectrum in the post-shock region.

3.3. Proton acceleration

Is there observational evidence for ion acceleration in SNRs ? How efficient is cosmic-ray acceleration ? What fraction of the shock energy can be tapped by the cosmic rays ? To answer these questions, we can search both for a possible modification of the hydrodynamics and for a direct spectral signature of the accelerated protons.

3.3.1. Back-reaction of the accelerated particle on the shock and hydrodynamics

For an efficient ion injection, a large fraction of the shock energy go into accelerated particles. The back-reaction of the accelerated particles modifies the shock structure (Ellison, 2000). The overall shock compression ratio gets larger (above a value of 4) and the post-shock temperature gets lower. Such a case was observed in the remnant 1E 0102.2-7219 in the Small Magellanic Cloud. With an observed

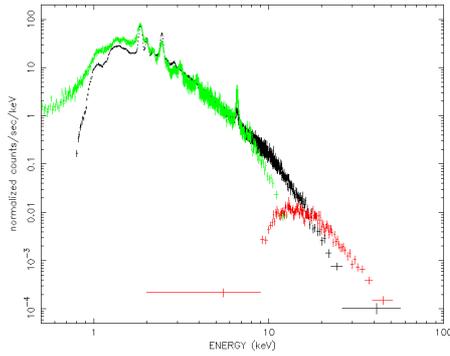

Fig. 2. Simulated *Simbol-X* spectrum of a region of 1 arcmin² in the west of Cas A for 30 ks observation. In green the *XMM-Newton* EPIC PN spectrum, in black and red the *Simbol-X* MPD and CZT spectra, respectively.

shock velocity of about 6200 km/s, the expected mean post-shock temperature is 45 keV. However, the electronic temperature measured with *Chandra* is less than 1 keV. Even in the case of complete non-equipartition between the electrons and the ions, namely $T_e/T_i = 1/1836$ at the shock, the Coulomb collisions predict a temperature larger than 2.5 keV. This is interpreted as a signature of efficient pro-

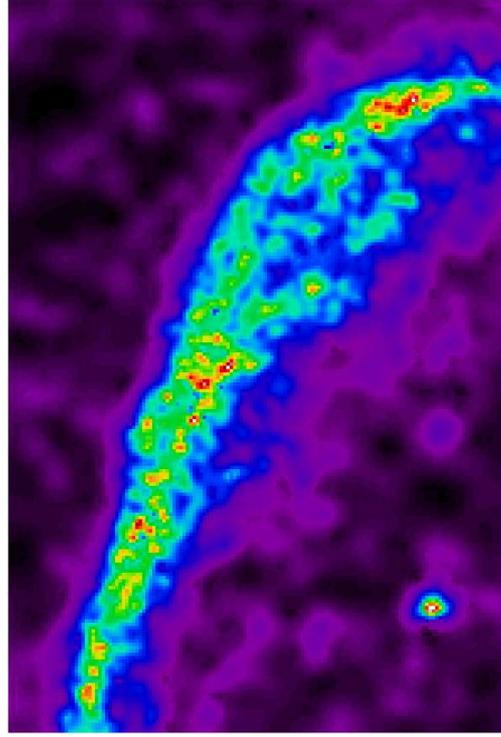

Fig. 3. Simulated *Simbol-X* image above 10 keV of the north-eastern synchrotron rim in SN 1006 for a 30 ks observation. The field of view is 10×10 arcmin².

ton acceleration at the shock (Hughes et al., 2000). In case of efficient proton acceleration, not only the shock structure is modified, but also the overall hydrodynamics giving rise to a narrower shocked region (Decourchelle et al., 2000; Ellison et al., 2004). This morphological feature of proton acceleration is observable in X-rays through the measurement of the ratio between the shock and contact discontinuity radii. In Tycho and Kepler's SNRs, this radii ratio is observed to be less than 1.1, while models without particle acceleration predict radius ratio of ≈ 1.18 (Decourchelle, 2005). Using a deep *Chandra* observation of Tycho's SNR, Warren et al. (2005) provided a measurement of the radii ratio as a function of azimuth and confirmed a smaller radii ratio than expected in the test-particle case, featuring efficient acceleration of protons at the

shock. One of the uncertainty in the measurement arises from the determination of the contact discontinuity radius which is affected by the development of Rayleigh-Taylor instabilities (Blondin & Ellison, 2001). This complicates the interpretation of the observed radii ratio.

3.3.2. Pion decay and TeV observations

A direct signature of accelerated protons is expected through pion decay emission in the GeV-TeV gamma ray range. However at these energies, a contribution of the Inverse Compton emission is expected as well and requires to be correctly estimated for a proper determination of contribution of the pion decay emission. This can be done by characterizing the population of TeV accelerated electrons responsible for the Inverse Compton emission through their synchrotron emission observed in the X-ray range and by estimating the magnetic field intensity (see sect. 3.2.2). Combining X-ray and gamma-ray observations is thus a fruitful way to estimate the pion decay emission in the TeV energy range. Ultimately, an unequivocal signature of accelerated protons is expected through gamma ray observations of the spectral feature associated to the pion decay. *GLAST*, to be launched early 2008, is expected to provide such observations.

3.4. Acceleration by secondary shocks

As discussed in section 2., a number of young SNRs do exhibit a hard X-ray tail (Allen et al., 1999). However, its origin is still unknown, due to the absence of spatially resolved spectroscopy above 10 keV. Only Cas A supernova remnant has been mapped above 10 keV, thanks to *XMM-Newton* (Bleeker et al., 2001). Its hard X-ray tail observed up to 40 keV was first interpreted as synchrotron emission (Allen et al., 1997). However, the *XMM-Newton* image in the 8-15 keV band revealed that the emission was mostly coming from the interface between the shocked ejecta and the shocked ambient medium, and not from the main blast wave. This finding is inconsistent with a synchrotron interpretation as it requires

to have high energy TeV electrons in the regions which have been shocked at earliest in the history of the remnant. This is impossible as the losses affecting the TeV electrons are very efficient and confine them close to the shock. Vink & Laming (2003) proposed that the emission at the interface was non-thermal bremsstrahlung due to particle acceleration at secondary shocks. The origin of these hard X-ray tails is still an open issue, for which *Simbol-X* is awaited.

4. Contributions of SIMBOL-X

In the field of supernova remnants, the major expected contributions of *Simbol-X* concern particle acceleration. It will be the first instrument with a full spectro-imaging capability above 10 keV, and a broad energy range covering at a good spatial resolution both the thermal and the non-thermal regimes. It is only with such a spectro-imaging capability that the contribution of each potential emission processus can be distinguished and quantified: thermal emission from a high temperature plasma, non-thermal bremsstrahlung from a population of suprathermal electrons, or synchrotron emission from TeV accelerated electrons. With its broad energy range, *Simbol-X* is well suited to investigate the coupling between thermal and non-thermal populations through the back-reaction of accelerated protons on the shock structure and on the overall hydrodynamics. With its spatially resolved spectroscopy capability above 10 keV, *Simbol-X* can study the physics of the acceleration of electrons, the physics at the interface between the ejecta and the ambient medium, as well as the physics at the shock through the heating of the electrons. The observation of the ^{44}Ti gamma ray lines is also an objective for *Simbol-X*, as discussed in these proceedings by Renaud et al.

The best potential SNR sources for *Simbol-X* are :

- the young ejecta-dominated Galactic SNRs. They are relatively bright sources, well adapted to the field of view. They do exhibit thermal and non-thermal emission, as well as a pronounced hard X-ray tail (see Cas A in Figs. 1 and 2).

- the specific sites of particle acceleration in synchrotron-dominated SNRs. They are relatively bright sources of hard X-ray emission (see SN 1006 in Fig. 3), showing strong spectral variations (below 10 keV).
